1922

**CERTIFICATE:** By direction of the Secretary of War, the matter contained herein is published as administrative information and is required for the proper transaction of the public business.

(11)

# RESERVE BENDING STRENGTH OF STRUTS.

The object of this investigation is to determine the comparative strength in bending of columns of various materials.

The struts are designed of square spruce, of Specification 10225 round steel tubes, of Specification 10227 round steel tubes and of round duralumin tubes, as columns with various lengths and axial loads.

The resulting columns are then investigated in bending, considering the column to be a simple beam, the maximum allowable concentrated load at the center computed and the results compared.

The columns are then investigated with combined axial and bending loads, each column being assumed to have an axial load equal to 80 per cent of the maximum allowable load, the allowable concentrated bending load at the center computed and the results compared.

## CONCLUSIONS.

Spruce and duralumin tube columns designed for the same lengths and axial loads have about the same strength in bending. However, when considered with reference to the weights of the resulting columns, the spruce columns are slightly stronger than the duralumin columns for all lengths and loads covered by this investigation with the exception of the columns designed for the smaller axial loads.

Duralumin tube columns are much stronger in bending than Specification 10227 steel tube columns designed for the same lengths and axial loads. Comparison with reference to their respective weights is even more favorable to the duralumin tube columns.

Columns of Specification 10227 steel tubes weigh a little less, in general, than columns of Specification 10225 steel tubes designed for the same lengths and axial loads. However, the Specification 10227 steel tube columns are much stronger in bending than the Specification 10225 steel tube columns, and the difference is accentuated when the comparison is made with reference to their respective weights.

When compared with reference to their respective strengths with combined axial and bending loads, the square spruce columns in general have a slightly better strength-weight ratio than the duralumin tube columns; the duralumin tube columns have a much better strength-weight ratio than the Specification 10227 steel tube columns; and the Specification 10227 steel tube columns have a much better strength-weight ratio than the Specification 10225 steel tube columns.

Curves were developed, see Figure 1, to show the efficiency of the columns in bending when the bending stresses are combined with axial loads. The spruce columns are slightly more efficient in the Euler range than the columns of other materials, and the Specification 10225 round steel tube columns are the most efficient in the Johnson range. The efficiency of the columns in bending is low excepting for columns with low values of  $L/\rho$ , and for the range of this investigation, the efficiencies decrease

rapidly as  $L/\rho$  approaches the dividing line between the Johnson and Euler ranges.

## ASSUMPTIONS.

All columns are assumed to be pin-ended.

The following strength properties are assumed:

Material.	Compressive strength (pounds per square inch).	Modulus of rupture (pounds per square inch).	Modulus of elasticity (pounds per square inch).
Spruce.....	5,500	10,300	1,600,000
Specification 10227 steel.....	90,000	110,000	30,000,000
Specification 10225 steel.....	36,000	55,000	28,000,000
Duralumin.....	35,000	55,000	10,000,000

The following weights are assumed:

Spruce.....	27 pounds per cubic foot
Duralumin.....	175 pounds per cubic foot
Specification 10227 steel.....	490 pounds per cubic foot
Specification 10225 steel.....	485 pounds per cubic foot

## COMPUTATIONS

Columns of each material are designed with lengths of 10 inches, 30 inches, 60 inches, and 100 inches.

or each length of the various materials columns are designed for axial loads of 1,000 pounds, 5,000 pounds, 10,000 pounds, and 20,000 pounds.

When the allowable load per square inch is greater than 50 per cent of the ultimate compressive strength of the material, Johnson's column formula is used:

$$\frac{P}{A} = f - \frac{f^2}{4C\pi^2 E} \times \left(\frac{L}{\rho}\right)^2$$

When the allowable load per square inch is less than 50 per cent of the ultimate compressive strength, Euler's column formula is used:

$$P = \frac{C\pi^2 EI}{L^2}$$

As the columns are assumed to be pin-ended, the constant "C" is equal to 1.0 in each case.

In designing the square spruce columns theoretical sizes are used.

In designing the steel and duralumin tube columns the nearest stock size is used, and the concentrated load in bending is corrected for the difference between the stock size and the theoretical size of the column.

Considering the designed columns to be simple beams, the maximum concentrated load at the center is computed by the following formula:

$$\begin{aligned} \text{The maximum moment} &= \frac{PL}{4} = M = \frac{fI}{y} \\ P &= \frac{4fI}{Ly} \end{aligned}$$

where  $P$  is the allowable concentrated load at the center.

FIG. 1.

The properties of the designed columns for various materials, lengths, and axial loads are shown in Tables 1, 2, 3, and 4.

The maximum concentrated bending loads for the various columns considered as simple beams are shown in Table 5.

In investigating the columns for a combined axial load and concentrated bending load at the center, the following method is used:

$F_c$  and  $F_b$  being assumed,  $f_c$  is computed for the column under consideration with an axial load equal to 80 per cent of the maximum allowable load. Substituting in the following formula, the value of  $f_b$  is obtained:

$$f_b + f_c = \frac{f_b}{f_b + f_c} \times (F_b - F_c) + F_c$$

$$f_b = \frac{F_b}{2} - f_c + \frac{1}{2} \sqrt{4F_c f_c - 4F_c f_c + F_b^2}$$

The maximum moment for a simple beam with a concentrated load at the center =  $M = PL/4$ .

$$M = M' \times \left(1 - \frac{P_1 L^2}{10 EI}\right) = \frac{PL}{4}$$

$$M' = \frac{f_b I}{y}$$

$$P = \frac{4f_b I}{Ly} \times \left(1 - \frac{P_1 L^2}{10 EI}\right)$$

where  $P$  = concentrated bending load at the center

$P_1$  = axial load.

The resulting allowable concentrated bending loads computed in combined compression and bending are to be found in Table 6.

Curves showing the efficiency of the resultant columns in combined compression and bending are shown in Figure 1. The ratio of the allowable bending load in combined compression and bending to the maximum allowable bending load is plotted as ordinates, and the values of  $L/\rho$  are plotted as abscissæ.

In designing the tube columns for the different lengths and loads the nearest stock size is used, the maximum allowable axial load computed for the size chosen,  $P_b$  computed for the size chosen and  $P'_b$  is then corrected as follows:

Let  $A$  = axial load used in design of column.

$B$  = maximum allowable axial load for the tube used.

$y$  = maximum concentrated bending load at center.

$x$  = corrected value of  $P_b$ .

$$x = \frac{Ay}{B}$$

The weights of the metal columns are corrected to the weight of the theoretical size in the same manner as the bending loads.

P'<sub>b</sub> is the maximum allowable concentrated bending load at the center of the column when the column is sustaining an axial load equal to 80 per cent of the maximum allowable load. As the nearest stock size was used in the design of the tube columns, the values of P'<sub>b</sub> have been corrected by proportion to the design axial load, as shown in note to Table 5.

The weights of the metal columns are corrected to the weight of the theoretical size by the same method as the bending loads.
